Retinal detachment is the separation of the neurosensory retina from the underlying retinal pigment epithelium. In pregnancy with hypertensive disorders, it is a very rare complication and usually seen bilaterally. Here, a case of bilateral serous retinal detachment and uterine atony in association with preeclampsia seen in the postpartum period of a term pregnant woman with no history of prior hypertension is presented.

Key Words: Preeclampsia, Serous retinal detachment, Uterine atony, Obstetric complications

Introduction

Retinal detachment is defined as the separation of the neurosensory retina from the underlying retinal pigment epithelium and is a very serious problem usually affecting middle-aged or older people.1 In pregnancy with hypertensive disorders, it is a very rare complication and usually seen bilaterally.2 Its pathogenesis still remains unknown but most likely related to the choroidal ischemia secondary to an arteriolar vasospasm.3 This vasospasm is explained with the placental thromboplastin that may be released into maternal circulation and activate the extrinsic coagulation system resulting with disseminated intravascular coagulation.3 Here, we want to present a case of bilateral serous retinal detachment and uterine atony in association with preeclampsia seen in the postpartum period of a term pregnant woman with no history of prior hypertension.

Case Report

A 28-year-old multiparous woman (gravida 3, para 3) with a 38 weeks of gestation admitted to the hospital with a complaint of labour pain. The patient’s body mass index was 22.6 kg/m² before pregnancy and she gained 12 kg during pregnancy. She had no history of smoking or drinking. Hypertension was diagnosed in her genetic family history and no other genetic disorders were detected. Her previous pregnancies were uneventful. Thus far there was no history of preeclampsia or any systemic diseases on her background and all laboratory tests were within normal limits before parturition. The patient delivered a 1820 gr female baby vaginally with an Apgar score of 7 at 1 minute and Apgar score of 9 at 5 minutes after about 3 hours of active labour. Neonatal admission to the neonatal intensive care unit (NICU) was mainly because of prematurity and the neonate was discharged after 4 days of follow-up.

After parturition, sharp curettage was to be performed due to placental retention. On the first hour of postpartum period, systemic hypertension above 180/100 mmHg was detected. The laboratory evaluation revealed 400 mg proteinuria in the urine sample evaluation, at this time thrombocyte count was determined 92000/µL and the severity of thrombocytopenia increased in several hours to 43000/µL. Blood urine nitrogen (BUN) and creatinine were detected 42 mg/dL and 1.7 mg/dL, respectively. Aspartate Aminotransferase (AST) was 44 U/L and Alanine Aminotransferase (ALT) was 22 U/L. The patient’s condition was considered to be severe preeclampsia. The patient complained of visual loss and diplopia bilaterally in 1 hour of follow-up. The urgent ophthalmologic evaluation revealed bilateral serous retinal detachments affecting predominantly the peripapillary area (Figure 1).

On the other hand, uterus was hypotonic concurrently. As postpartum hemorrhage was not been able to be controlled with medication, bilateral hypogastric artery ligation and B-Lynch suture were performed by laparotomy in turn to control bleeding. Her hemoglobin concentration was 11.2 mg/dL at admission, 7.3 mg/dL at the beginning of the operation, respectively. During the operation, with a decrease of 5 units in
hemoglobin concentration, the patient received 5 units of red blood cell transfusion and 5 units of fresh frozen plasma. In spite of all these procedures, hysterectomy was to be performed at last to control hemorrhage. The postoperative period was uneventful and the mother tolerated the operation without any serious complications. Serious retinal detachment regressed spontaneously in the third day of postpartum period. She was discharged at the 7th day of postoperative period. Complete regression of the retinal detachments was observed within 2 weeks with epithelial pigment changes and the patient had her recovery of vision without any serious complications.

Discussion

Hypertension affects both the mother and the newborn to varying degrees. Preeclampsia is a pregnancy specific disease with unknown causes that affects approximately 5% of all pregnant women and still remains a leading cause of maternal and perinatal morbidity and mortality.4 In a patient with preeclampsia, maternal and perinatal outcomes may differ by multi-organ involvement with different clinical features including renal, cerebral, hepatic disorders with life threatening results.

Although the visual system can be affected in 30-100% of the preeclamptic patients, one of the least affected end-organ is retina.2 Wide ranges of ocular manifestations resulting from preeclampsia as retinopathy, serous retinal detachments, optic neuropathy and occipital cortical changes were reported in the literature.5 Serous retinal detachment affecting 0.2-2% of severe preeclamptic patients is to be considered as a rare but notable complication with the risk of permanent blindness.5 But in most cases, the detachment regresses in parallel to regression of the toxemia without any serious damages. Spontaneous serous retinal detachment may occur both at antepartum and postpartum periods and resolves with a return to normal visual function within the first few weeks postpartum.7 This case illustrates that when the patient develops another obstetric complication such as uterine atony which is the most common cause of postpartum hemorrhage, it could be a more complex situation to succeed in.

In conclusion, it should be kept in mind that preeclampsia is a complex, multi-organ affected disease that patients should be managed more carefully both at antepartum and postpartum periods including detailed ophthalmologic examination.
